#### Chick-fil-A tests its first plant-based sandwich

By DEE-ANN DURBIN February 9, 2023

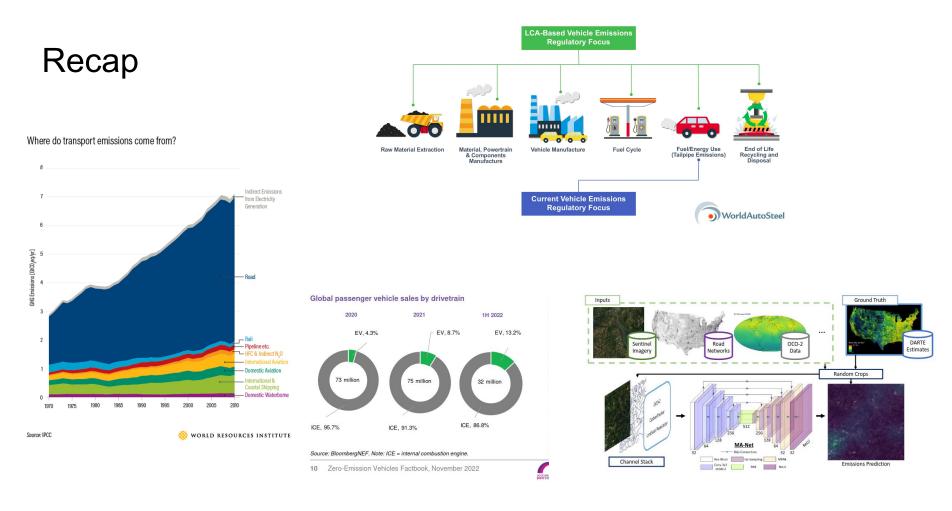

Chick-fil-A is jumping on the plant-based bandwagon.

The Atlanta chain said Thursday that it's testing its first plant-based entrée \_\_\_ a breaded cauliflower sandwich \_\_\_ at restaurants in Denver; Charleston, South Carolina; and the Greensboro, North Carolina, area. The test begins Feb. 13.

Chick-fil-A said its culinary team spent four years developing the sandwich after guests told the chain they wanted to add more vegetables to their diets. Chick-fil-A tested mushrooms, chickpeas and chopped vegetables formed into patties but kept returning to cauliflower for its mild flavor.

Like Chick-fil-A's signature chicken sandwich, the cauliflower steak is marinated, breaded, pressure-cooked and then served on a bun with two pickle slices.

Chick-fil-A is a relative latecomer to the plant-based fast food scene. Burger King started selling its Impossible Whopper \_\_\_\_\_ featuring a plant-based burger made by Impossible Foods \_\_\_\_\_\_ in 2019. Starbucks launched an Impossible sausage sandwich in 2020. McDonald's debuted its McPlant burger \_\_\_\_\_ developed with Beyond Meat \_\_\_\_\_\_ in the United Kingdom in 2021. And KFC began selling Beyond Meat nuggets last year.

#### Per capita emissions per country

Food emissions don't exactly follow the normal trend of wealthier nation = higher emissions

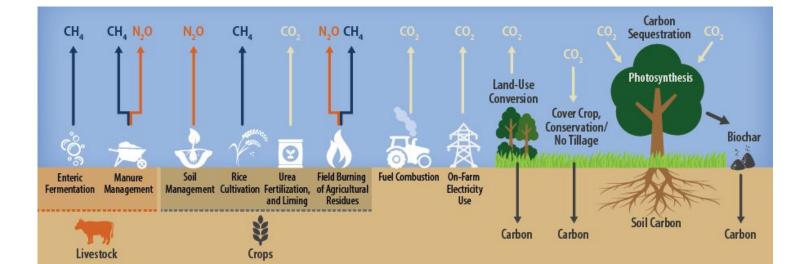

Agriculture accounted for 10% of the EU's total greenhouse-gas emissions in 2012. A significant decline in livestock numbers, more efficient application of fertilisers, and better manure management reduced the EU's emissions from agriculture by 24% between 1990 and 2012.

However, agriculture in the rest of the world is moving in the opposite direction. Between 2001 and 2011, global emissions from crop and livestock production grew by 14%. The increase occurred mainly in developing countries, due to a rise in total agricultural output. This was driven by increased global food demand and changes in food-consumption patterns due to rising incomes in some developing countries. Emissions from enteric fermentation increased 11% in this period and accounted for 39% of the sector's total greenhouse-gas outputs in 2011.

#### Agriculture: sources and sinks

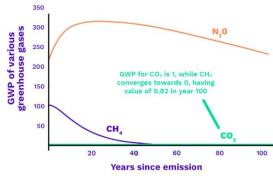

- Farming of plants and animals can capture as well as release CO2.
- Farming requires land that may have been used for other purposes
- Modern farming practices lead to far more emissions than reductions in GHGs

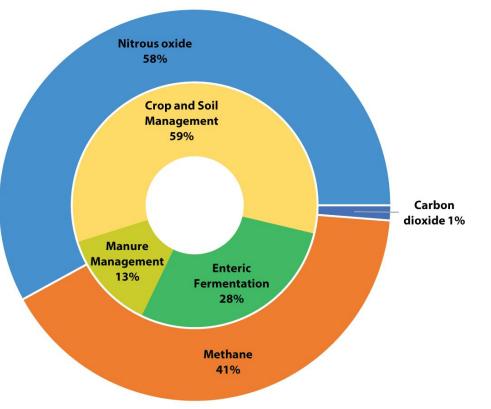

### Emissions (direct) from agriculture

Carbon dioxide makes up only a small fraction of emissions from the agriculture industry.

Global Warming Potential (GWP) Changes Over Time

Soils store and release carbon through interaction with plants, animals, and microbes

Modern fertilizer production and use causes a variety of emissions, as well as other environmental problems.

#### **The Triple Threat of Nitrogen Fertilizers**

Synthetic nitrogen fertilizers, which are used heavily on corn, the country's most widely grown crop, contribute to climate change in three key ways.

https://insideclimatenews.org/news/24102018/infographic-far m-soil-carbon-cycle-climate-change-solution-agriculture/

Better agricultural practices (sometimes called regenerative farming) can help soil sequester more carbon.

Because of the large amount of land dedicated to farming, small changes can have big impacts.

### Emissions from specific foods

#### Greenhouse gas emissions per kilogram of food product

Emissions are measured in carbon dioxide equivalents (CO2eq). This means non-CO2 gases are weighted by the amount of warming they cause over a 100-year timescale.

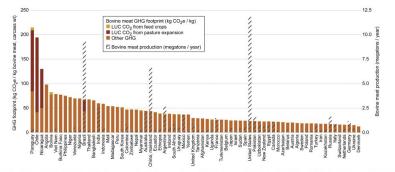

Source: Poore, J., & Nemecek, T. (2018). Reducing food's environmental impacts through producers and consumers. OurWorldInData.org/environmental-impacts-of-food • CC BY Note: Greenhouse gases are weighted by their global warming potential value (GWP100). GWP100 measures the relative warming impact of one molecule of a greenhouse gas, relative to carbon dioxide, over 100 years.

## Emissions per 100g of protein

Emissions estimates have wide variability due to different farming practices.

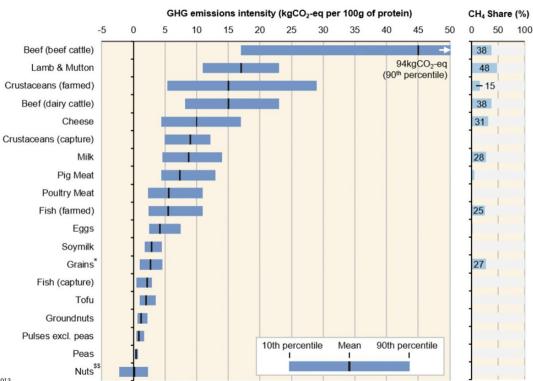

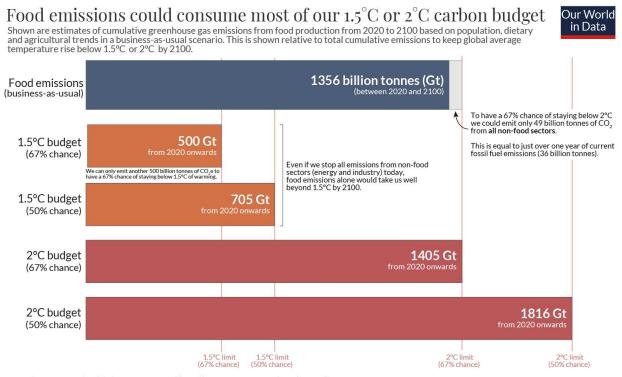

Fig. 3. Per-kilogram GHG footprints of bovine meat, by producing country, shown for countries that produced over 100 000 metric tons in 2011-2013.

#### Significant changes to agriculture are necessary to avoid unsustainable warming

Note: This is measured in global warming potential (GWP\*) CO<sub>2</sub> warming-equivalents (CO<sub>2</sub>-we). Source: Michael Clark et al. (2020). Global food system emissions could preclude achieving the 1.5° and 2°C climate change targets. *Science*.

### What needs to be done, according to the IPCC

#### A change in diets (and culture)

Shifting consumption towards plant-based diets has "high mitigation potential", says the report. There is *robust evidence* that "diets high in plant protein and low in meat and dairy" make for lower GHG emissions.

IPCC estimates with *high confidence* that shifts to sustainable healthy diets have a "technical potential" to reduce emissions by 3.6GtCO2e, with a range of 0.5 to 8GtCO2e.

Key enablers for these shifts could include creating "novel narratives" in the media and entertainment industry to "help to break away from the established values, discourses and the status quo". These might portray plant-based diets as healthy and natural, for example.

The IPCC report explores other measures that could be used to influence choices in the food sector, including taxes or carbon pricing on food, both of which it says would be "regressive", meaning they disproportionately burden poorer members of society. Instead, it points to options including marketing regulations, procurement policies, dietary guidelines, labelling and "nudges".

https://www.carbonbrief.org/in-depth-qa-the-ipccs-sixth-assessment-on-how-to-tackle-climate-change/

### What needs to be done, according to the IPCC

#### New technologies

Beyond dietary changes, the report says there is *limited evidence* – but *high agreement* – that a suite of "emerging technologies" could bring "substantial reduction in direct GHG emissions from food production". These include plant-based alternatives to animal products, cultured meat, and "controlled environment agriculture", which it describes as "hydroponic or aquaponic cultivation systems that do not require soil".

These technologies typically have lower water, land and nutrient footprints, but as some of them are energy-intensive, they need to have access to low-carbon energy.

### What needs to be done, according to the IPCC

#### Focus on highest emitters globally

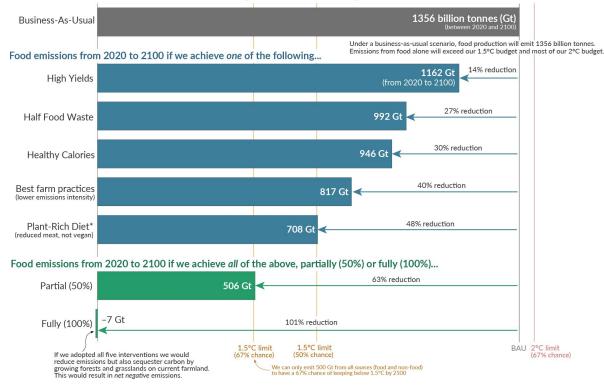

Global food supply chains have a strong influence on per-capita food consumption emissions, particularly for red meat and dairy, the report notes, such that the highest per-capita food-related emissions "do not correlate perfectly with the income status of countries". In other words, even relatively poorer countries may have a high per-capita food footprint.

As a result, the report says "it is crucial to focus on high-emitting individuals and groups within countries, rather than only those who live in high-emitting countries, since the top 10% of emitters live on all continents and one third of them are from the developing world".

#### How can we reduce global greenhouse gas emissions from food?

This is measured in global warming potential (GWP\*) CO<sub>2</sub> warming-equivalents (CO<sub>2</sub>-we).

\*Based on the EAT-Lancet Planetary Health diet which reduces but does not eliminate meat or dairy consumption. Source: Michael Clark et al. (2020). Res. Commun.* **3** 045002 DOI 10.1088/2515-7620/abf15f

#### Conclusions

Using our RF predictive modeling framework, we created a map of nitrate concentrations leached from the root zone of agricultural soils across the Netherlands for the year 2017. With our model, we interpolate the nitrate concentrations measured at the farm level on a national scale. In our model, the most important variables for the prediction are variables related to the present of grasslands (land use, crops), and variables related to altitude, soil (soil type, clay and organic matter content), groundwater level and N and P emissions to surface water. The explained variance and statistical

Air Quality, Atmosphere & Health 15, 575–589 (2022) | Cite this article 303 Accesses | 5 Citations | Metrics

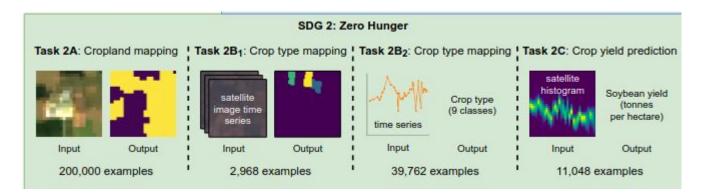

#### Conclusion

Measurements were carried out in three experimental pig's barns with three different types of concentrated diets to characterize manure production. The quantity of manure produced per pig, moisture content, DM, ash, and VS contents increased with the mass and feed intake of pigs. Body mass ranged from 60 to 90 kg a pig produced around 3.35 kg of manure per day consisting of 66% moisture content and 34% DM. The manure's ash content was 28% DM (0.47 kg pig<sup>-1</sup> day<sup>-1</sup>), while the VS was 72% DM (1.15 kg pig<sup>-1</sup> day<sup>-1</sup>). In the present study, the pigs' mass and the quantity of feed intake were used as explanatory variables to model the CH<sub>4</sub> production rate. Five statistical and ML algorithms were evaluated based on three statistical qualitative parameters for CH<sub>4</sub> emission modelling. The results showed that the regression-based models performed better than the ANN model. Moreover, the RR model was selected as the best model among those models in predicting CH<sub>4</sub> production. This priority for

#### Precision agriculture

"We propose a path towards more sustainable agriculture, considering plant development an optimization problem with respect to certain parameters, such as yield and environmental impact, which can be optimized in an automated way. Specifically, we propose to use reinforcement learning to autonomously explore and learn ways of influencing the development of certain types of plants, controlling environmental parameters, such as irrigation or nutrient supply, and receiving sensory feedback, such as camera images, humidity, and moisture measurements. The trained system will thus be able to provide instructions for optimal treatment of a local population of plants, based on non-invasive measurements, such as imaging"

Animal welfare

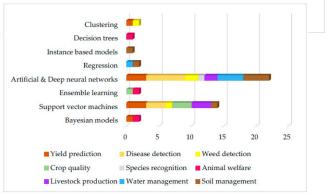

Weed detection

Crop quality

Machine learning has emerged with big data technologies and high-performance computing to create new opportunities for data intensive science in the multi-disciplinary agri-technologies domain. In this paper, we present a comprehensive review of research dedicated to applications of machine learning in agricultural production systems. The works analyzed were categorized in (a) crop management, including applications on yield prediction, disease detection, weed detection crop quality, and species recognition; (b) livestock management, including applications on animal welfare and livestock production; (c) water management; and (d) soil management. The filtering and classification of the presented articles demonstrate how agriculture will benefit from machine learning technologies. By applying machine learning to sensor data, farm management systems are evolving into real time artificial intelligence enabled programs that provide rich recommendations and insights for farmer decision support and action.

Goal: Predict the amount carbon stored in soil based on other factors of the land that normally correlate with it.

### Brainstorm

What kind of data would you want to have to be able to approach this problem?

What kind of methods would you apply?

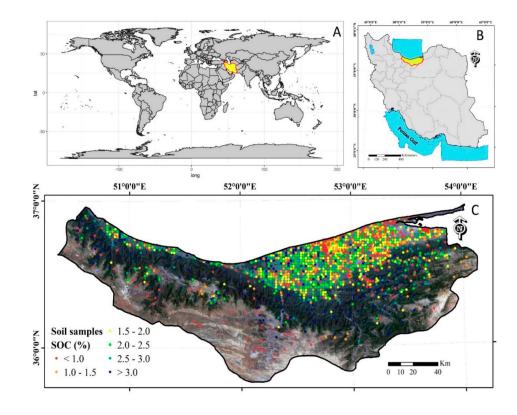

How would you measure success?

If successful, how could this system be useful?

## Data: Target variable

Northern region of Iran where some on-the-ground tests of soil carbon have been made

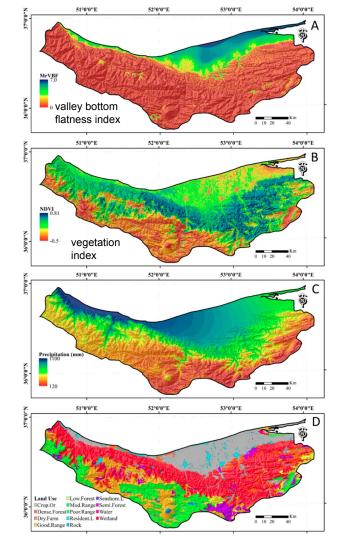

Dataset contains 1879 composite surface soil samples from two main sources (Figure 1). More than half of the data (1055 samples) were derived from five Master of Science (M.Sc.) research projects in the soil science department at Sari Agricultural Sciences and Natural Resources University (SANRU) [60,61,62,63,64]. These samples were collected using a simple random sampling scheme mostly in *uncultivated areas*. The rest of the dataset comes from soil surveys performed by the Agricultural Research Education and Extension Organization (AREEO) and the Ministry of Jahad-e-Keshvarzi in Sari, Northern Iran. These samples were mostly collected in *cultivated areas* spread across the province using a grid sampling scheme with a 2000 m grid interval.

### **Data: Predictors**

The authors collected a wide range of data that could be predictive of soil carbon.

Regressors included variables derived from remotely sensed imagery (60 variables from Landsat 8 and MODerate-resolution Imaging Spectroradiometer, MODIS), terrain attributes (30 variables), climatic data (10 variables), and five categorical data (e.g., soil map and land use map).

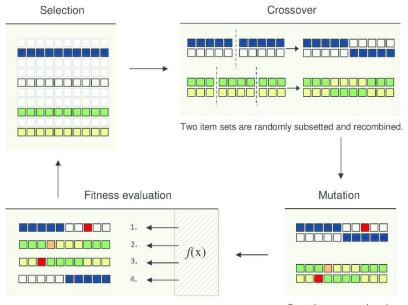

### Methods: Feature selection

# Genetic algorithm is used to pare down the list of predictors.

#### 2.4. Selection of Auxiliary Variables Using Genetic Algorithms (GA)

Instead of taking all 105 environmental auxiliary variables into consideration for a predictive ML algorithm, the feature selection method reduces the number and collinearity of the auxiliary variables. The most informative auxiliary variables should be inserted into the algorithms with the aim of high accuracy of the ML algorithms for SOC prediction [9,16,25]. The selection of the significant environment auxiliary variables is a preprocessing step for ML algorithms to remove redundant and irrelevant variables. For this study, one of the most advanced algorithms for feature selection, namely the genetic algorithm (GA), was used to select the most appropriate auxiliary data to be fed as inputs to the ML algorithms [16]. GA is able to select those auxiliary data that are not only essential but improve performance as well. Moreover, GA can manage the nonlinear relationships between SOC and auxiliary data [70].

By mimicking natural biological evolution, the GA which is a heuristic search algorithm provides the best value for a function [51]. A GA feature selection process starts with an initial random population consisting of individuals. The individuals, representing subsets of auxiliary data, are encoded as binary in which 1 represents if the feature is selected and 0 otherwise [71]. Then three primary operations including selection, crossover, mutation repeat until a stopping criterion is reached. The selection operations were for selecting the two fittest individuals for reproduction (i.e., the solutions providing the lowest root mean squared error, RMSE). The crossover recombines two individuals to create new ones which may be better. The mutation operator introduces alteration in a small number of individuals. The process of selection, crossover, and mutation continues until a termination condition is satisfied [48,52]. Importantly, for each generation, it is necessary to assign a fitness value to each individual in the population so that the RMSE values are calculated by fitting the random forest model [46,48,52].

Item sets are evaluated according to a fitness function; results in turn influence selection probability in the next iteration.

Some items are replaced with items from the initial item pool.

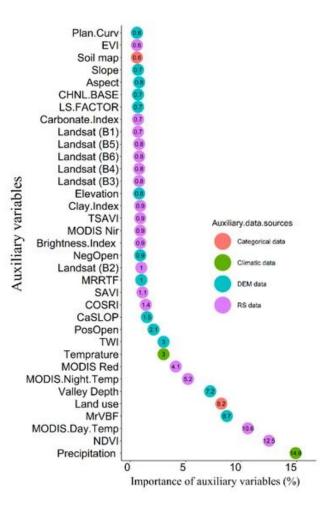

### Methods: Feature selection

# GA selected 35 predictors out of 105 environmental variables.

#### 2.4. Selection of Auxiliary Variables Using Genetic Algorithms (GA)

Instead of taking all 105 environmental auxiliary variables into consideration for a predictive ML algorithm, the feature selection method reduces the number and collinearity of the auxiliary variables. The most informative auxiliary variables should be inserted into the algorithms with the aim of high accuracy of the ML algorithms for SOC prediction [9,16,25]. The selection of the significant environment auxiliary variables is a preprocessing step for ML algorithms to remove redundant and irrelevant variables. For this study, one of the most advanced algorithms for feature selection, namely the genetic algorithm (GA), was used to select the most appropriate auxiliary data to be fed as inputs to the ML algorithms [16]. GA is able to select those auxiliary data that are not only essential but improve performance as well. Moreover, GA can manage the nonlinear relationships between SOC and auxiliary data [70].

By mimicking natural biological evolution, the GA which is a heuristic search algorithm provides the best value for a function [51]. A GA feature selection process starts with an initial random population consisting of individuals. The individuals, representing subsets of auxiliary data, are encoded as binary in which 1 represents if the feature is selected and 0 otherwise [71]. Then three primary operations including selection, crossover, mutation repeat until a stopping criterion is reached. The selection operations were for selecting the two fittest individuals for reproduction (i.e., the solutions providing the lowest root mean squared error, RMSE). The crossover recombines two individuals to create new ones which may be better. The mutation operator introduces alteration in a small number of individuals. The process of selection, crossover, and mutation continues until a termination condition is satisfied [48,52]. Importantly, for each generation, it is necessary to assign a fitness value to each individual in the population so that the RMSE values are calculated by fitting the random forest model [46,48,52].
